\begin{abstract}

The purpose of this systematic review was to analyze the effect of decreased, restored, or increased femoral offset on patient reported outcomes (PROs) following hip arthroplasty. Databases were searched according to the Preferred Reporting Items for Systematic Reviews and Meta-analyses guidelines. With regard to Harris Hip Score, two studies reported superior outcomes for the increased femoral offset group, one study reported superior outcomes for a restored offset group, and the final study reported favorable outcomes for the decreased offset group. Patients with restored offset following arthroplasty may demonstrate superior PROs.

\end{abstract}

\section{Introduction}

Soft-tissue tension following hip arthroplasty has been shown to have an effect on patient reported outcomes.\textsuperscript{1–3} Femoral offset (FO), defined as the distance between the center of the femoral head and the anatomical axis of the femur, affects soft-tissue tension following arthroplasty.\textsuperscript{4–9} Multiple variables such as the design of the implant, the diameter of the head, and the positioning of the stem within the femoral canal, can influence postoperative femoral offset.\textsuperscript{10,11} Current literature shows that restoration of optimal FO improves the abductor lever arm and results in increased survivorship, as well as reduced implant wear in total hip arthroplasty (THA).\textsuperscript{12,13} Lack of restoration can lead to a host of complications including loss of abductor tension, prosthetic joint dislocations, gait disturbances, increased edge loading on the acetabular component, and polyethylene wear.\textsuperscript{1,3,5–7} Excessive FO can increase tension on the abductor muscles, which may result in pain, reduced function, and increased polyethylene wear.\textsuperscript{2,11} In order to help navigate offset restoration, implant components with varying degrees of offset combinations have been devised. Likewise, multiple reports have commented on outcomes of THA at varying femoral offset.\textsuperscript{2,14} The purpose of this systematic review was to analyze the effect of decreased, restored, or increased femoral offset on patient reported outcomes (PROs) following hip arthroplasty. Our hypothesis was that patients with increased femoral offset would demonstrate superior outcomes.

\section{Methods}

In March 2019, we performed a comprehensive literature search using the PubMed, Embase, and Cochrane databases to identify articles that examined the relationship between femoral offset and functional outcomes following hip arthroplasty. The search followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) guidelines\textsuperscript{15} and utilized the following key words: arthroplasty, femoral offset, patient reported outcomes. The exact search algorithm is provided in the Appendix.

After conducting an initial abstract review, two reviewers (XXX and YYY) examined the full text to select relevant studies. In any cases of disagreement, a third reviewer (ZZZ) helped the group reach consensus. Studies were included in our analysis if they reported (1) preoperative or postoperative femoral offset following arthroplasty and (2) minimum one-year patient reported outcomes. Exclusion criteria were case series, technique articles, studies with less than one-year follow-up, and studies not published in the English language.
When available, we reported patient demographics, mean follow-up time, type of replacement, preoperative offset discrepancy, postoperative offset, physical examination findings, native abductor lever arm, patient reported outcomes (PROs), and complications in the selected studies.

2.1. Quality assessment & data analysis

Two authors independently assessed each selected article using the validated Methodological Index for Non-randomized Studies (MINORS)\textsuperscript{16} criteria. There were no cases of disagreement in MINORS scoring.

The standardized mean difference (SMD) was calculated to compare the effect size of femoral offset on PROs. As described by Kemp et al., the SMD was calculated by dividing the difference between the postoperative and preoperative outcome scores by the standard deviation of the respective preoperative score.\textsuperscript{17} If the standard deviation was not provided, it was estimated in the method described by Griffin et al., which includes using the range of the respective preoperative score.\textsuperscript{18} The standard error (SE) of the SMD was calculated in a method described by Kelley et al.;\textsuperscript{19} then, the 95% confidence interval (CI) was calculated using the formula SMD ± 1.96 x SE.\textsuperscript{17} The magnitude of the effect size was analyzed using the threshold literature values of SMD: weak, SMD between 0.2 and 0.49; moderate, SMD between 0.5 and 0.8; strong, SMD ≥ 0.8.\textsuperscript{20}

3. Results

Our literature search generated a total of 117 unique studies. Following a preliminary abstract review, 17 articles were selected for full-text review. There was one study that examined the relationship between stem type and PROs, three studies that did not report PROs, one study that did not report minimum one-year follow-up, and two studies that were written in the Chinese language. Ten studies, with 1,738 hips in total, met the inclusion criteria.\textsuperscript{12,14,21} A flowchart of our search strategy is provided in Fig. 1. MINORS and Level of Evidence scores are summarized in Table 1.

There were eight studies that reported outcomes following a total hip arthroplasty (THA)\textsuperscript{12,14,22,25,28} and two studies that reported outcomes following hemiarthroplasty.\textsuperscript{21,24} The mean age of all hips included in our study was 69.1 years (range 25–99), and all studies included minimum one-year follow-up.\textsuperscript{12,14,21–28} Six studies divided their respective cohorts into sub-categories using a threshold for postoperative\textsuperscript{12,14,22,25,26,28} femoral offset. To define reported offset, one study used the difference between height adjusted offset and actual offset,\textsuperscript{14} and four studies reported global offset, which was equal to the sum of the femoral offset and cup offset.\textsuperscript{9,23,25,27}

3.1. Functional outcomes

In total, the selected studies used twelve patient reported outcome (PROs): the Harris Hip Score (HHS), the Western Ontario McMaster Universities Index (WOMAC), the Oxford Hip Score (OHS), the EQ-5D health questionnaire (EQ-5D), the mental and physical portions of the Short Form Survey (SF-12P, SF-12M), the Hip disability and Osteoarthritis Index Score (HOOS), the Merle d’Aubigné-Postel Pain Score (PMA), the Instrumental Activities of Daily Living (IADL), the Modified Barthel Index, a Timed Up and Go (TUG), and a Numerical Pain Rating Scale (NPRS), as described by Downie et al.\textsuperscript{27}

The WOMAC index was the most commonly reported PRO, with five of ten studies including it in their analysis.\textsuperscript{14,25–28} For their entire patient population, three studies reported significant improvement (P < 0.05) in WOMAC scores postoperatively compared to preoperatively,\textsuperscript{14,25,26} and the other two studies did not comment on significance.\textsuperscript{27,28} One study showed superior WOMAC scores for the decreased offset group,\textsuperscript{14} another study showed superior WOMAC scores for the restored and increased group,\textsuperscript{25} and the final study did not show a significant difference in WOMAC scores between the decreased, restored, and increased groups.\textsuperscript{26}

The Harris Hip Score (HHS) was reported in four studies, making it the second most utilized PRO.\textsuperscript{12,21,24,26} With regard to HHS, two studies reported superior outcomes for the increased FO group,\textsuperscript{1,26} one study reported superior outcomes for a restored offset group (compared to unrestored),\textsuperscript{24} and the final study reported more favorable outcomes for the decreased FO group following hemiarthroplasty (68 ± 20).\textsuperscript{21}

Finally, PMA was reported in two studies,\textsuperscript{22,26} one of which reported greater range of motion and maximal swing speed in the restored and increased groups compared to the decreased group,\textsuperscript{26} while the other reported a significant improvement in the low FO cohort.\textsuperscript{22}

Two studies reported outcomes following hemiarthroplasty, and one study found a positive correlation between increased FO and PROs,\textsuperscript{21} while the other study found superior PROs in the restored offset group compared to patients with increased or decreased FO.\textsuperscript{24} Additional PROs are provided in Table 2.

Two studies reported muscle strength and range of motion for their cohorts.\textsuperscript{25,26} The decreased cohorts exhibited less postoperative abductor strength, decreased hip adduction, reduced range of motion in the knee, and a lower swing speed compared to the restored or increased groups.\textsuperscript{25,26} Finally, complications reported in the reviewed articles are shown in Table 3.

3.2. Sub-analysis of effect size of offset on outcomes

Four studies (1) sub-categorized their patient populations into a decreased, restored, and increased group and (2) reported preoperative and postoperative PROs for each group.\textsuperscript{14,25,26,28} A summary of how each study divided their cohort is provided in Table 4. All four studies that reported WOMAC reported a large effect size (SMD > 0.8) for the low, normal, and high offset groups.\textsuperscript{24} Mahmood et al. showed a large effect size (1.46, 1.95, respectively), for the low and normal offset groups, with respect to EQ-5D and a moderate effect size (0.53) for the high offset group.\textsuperscript{25} Further, Sariaily et al. reported a large effect size (≥ 3) for the low, normal, and high offset groups in HHS, HOOS, and PMA, with the high offset group experiencing the greatest effect.\textsuperscript{26} One study reported SF-12P and SF-12M scores, and the effect size was weak in all groups with regard to SF-12P and large in all groups with respect to SF-12P.\textsuperscript{28} A forest plot illustrating the effect sizes is presented in Fig. 2.

4. Discussion

Current literature suggests the attained femoral offset following hip arthroplasty affects patients’ postoperative PROs, muscle strength, and range of motion. This study aimed to investigate the effect of varying offset on PROs following hip arthroplasty. Ten studies were reviewed, which provided PROs and functional findings for patients with decreased, restored, and increased FO compared to their native offset. All three treatment groups demonstrated significant improvement in PROs, however, the restored offset groups showed more consistent improvement compared to the decreased or increased groups.

There is a paucity of literature regarding the optimal offset following hip arthroplasty. Judge et al. established a threshold of 44 mm for female patients, where an offset of > 44 mm was associated with better functional outcomes.\textsuperscript{30} In their cohort of 1,431 patients, the authors found higher preoperative outcomes and greater femoral offset were strong predictors for improved five year postoperative outcomes.\textsuperscript{30} Our selected studies did not establish a blanket threshold for femoral offset, but rather examined the effect of relative femoral offset, compared to baselines measures, on patient reported outcomes. While the effect of the femoral offset on THA outcomes varied between studies, the greatest proportion of studies found that restored postoperative femoral offset lead to superior PROs. With regard to hemi-
arthroplasty, there seems to be a slight advantage to either restoring or over-restoring offset. Of the two studies reviewed, one study found superior outcomes in the increased offset group and the other for the restored group, respectively.21 The authors concluded that the improved range of motion was driven by delayed osseous impingement. Furthermore, McGrory et al. found a positive correlation between increased femoral offset, range of abduction, and abductor strength in total hip arthroplasty (THA) patients.7 Accordingly, in our systematic review, Mahmood et al.25 reported decreased postoperative abductor strength and greater use of walking aids in the decreased FO group relative to the restored and the increased FO groups. Additionally, Sariali et al.26 reported significantly reduced range of motion at the knee, lower swing speed in the operative limb, and decreased hip adduction for the decreased FO group, compared to the restored and increased FO groups. Further, Takao et al. found that decreased FO was significantly associated with increased leg length discrepancy and increased abduction.27

Four studies reported femoral offset as the sum of the femoral offset and cup offset (global offset).9,23,25,27 In three (75%) studies, inferior functional outcomes were found in the decreased offset group.23,25,28 In a separate study, Bjarnason et al. found a stronger correlation between

a Used global offset = femoral offset + cup offset.
femoral and global offset when compared to acetabular and global offset, suggesting that femoral offset alone may be a fair approximation of global offset. Addition, Clement et al. showed that femoral offset was more predictive of greater postoperative outcomes than global offset, independently. Both Bjarnason et al. and Clement et al. show that the acetabular component of the global offset does not play a significant role in the assessment of the abductor lever arm. Hence, although global offset seems to add more information compared to the FO, it may not add substantial value.

In summary, it is evident that FO has an effect on both functional and clinical patient reported outcomes. Setting a target FO during preoperative planning should help facilitate reconstruction of the optimal FO. In addition, accurate assessment of FO intraoperatively should be done in order to help confirm that the desirable FO was achieved. In cases were the reconstructed FO cannot be achieved, the surgeon should be aware how lack of restoration may affect overall function of the hip arthroplasty.

4.1. Strengths

The standardized mean difference for three different offset groups was calculated for select studies to illustrate the varying effect of offset on PROs and address the notion that statistical significance does not equate clinical significance.
4.2 Limitations

We acknowledge the heterogeneity in our studies, as evidenced by the MINORS scoring system. There were varying definitions of decreased, restored, and increased OS in our analysis (Table 3). In addition, two included studies with 227 hips, examined the effect of offset on hemiarthroplasty.\(^{21,24}\) The effect size was dependent on the standard deviation of measurements of respective PROs, which differed greatly between study populations. Further, some studies did not show a significant difference in PROs between the decreased, restored and increased groups, which could be attributed to the “ceiling effect” of select patient reported outcomes.\(^{23,34}\)

5. Conclusion

Patients with restored femoral offset following arthroplasty may demonstrate superior patient reported outcomes compared to patients with increased or decreased femoral offset. Furthermore, patients with decreased femoral offset tend to exhibit inferior PROs and functional outcomes.
